

Improving probabilistic weather forecasts using seasonally varying calibration parameters

Stephen Jewson*

February 2, 2008

Abstract

We show that probabilistic weather forecasts of site specific temperatures can be dramatically improved by using seasonally varying rather than constant calibration parameters.

1 Introduction

Different users of weather forecast are interested in different things. One particular group of users, including weather derivatives traders, is most interested in probabilistic forecasts at specific locations. The production of such forecasts on the 0-10 day timescale is what we will consider in this article. We will derive our forecasts from the output of numerical weather prediction models, as is usual. This output contains a lot of information about the future weather but needs processing in order to be directly relevant to individual sites, which are not represented in the models. This processing step, usually known as *calibration* or *downscaling* can usefully be cast as a classical (i.e. non-Bayesian) statistical problem. In this framework a mixture of climatology and the output from the model are used as predictors and the observations that we wish to predict are the predictand.

Forecast calibration can be performed for any weather variable, but we will focus on temperature. For temperature anomalies¹ a good starting point for the calibration model is a standard linear regression taking the ensemble mean as the single predictor, and the distribution of possible future temperatures as the predictand. Linear regression has been used as a calibration model for at least 30 years, although it is only recently been fully appreciated that it gives a good probabilistic forecast, rather than just a good forecast of the expected temperature. The challenge is now to build models that perform better than linear regression, and that is the subject of this article. We have described the testing of a number of models versus linear regression in previous articles, and have generally found it hard to beat by more than minute amounts. For instance, we have tried to improve forecast skill by using the ensemble spread as a predictor of uncertainty (Jewson et al. (2003) and Jewson (2003c)), but found only a small benefit. We have also tried to improve the forecast by relaxing the assumption of normality and replacing the normal distribution with a kernel density, but in that case found almost no benefit at all (Jewson, 2003b). In another study we investigated whether the benefit of using an ensemble versus a single forecast arises more from the information content of the ensemble mean or the ensemble spread (Jewson, 2003a). The answer is very clear: the ensemble mean is vastly more useful. This suggests that the best way to beat linear regression might be to improve the forecast of the mean, rather than the forecast of the spread, and that is the approach we follow below.

How could we improve the forecast of the mean? There is a long list of methods we might consider, including:

- using non-linear models such as neural nets
- using predictors from other locations
- using lagged predictors
- using multiple models

¹from which the mean and seasonal cycle have been removed

- using seasonally varying parameters

These are all probably worthy of investigation. However in this paper we will only address the last of these: can we beat constant parameter linear regression by allowing the parameters to vary seasonally? On the one hand, from a meteorological point of view, this seems a very reasonable approach since in the climate one usually finds that everything varies seasonally. On the other hand, as devotees of parsimony, we balk at this approach. In a seasonal parameter model each of the parameters in the regression becomes (at least) 3 parameters. Thus a 3 parameter model becomes a 9 parameter model. For such a model to be better, the seasonality in the mapping from model forecast to observed temperature had better be rather strong.

The idea of using seasonally varying parameters is somewhat similar to a method currently used by some National Meteorological Services for the calibration of single forecasts which builds the calibration models using only recent training data (e.g. data for the previous 90 days). This method automatically captures some aspects of seasonality because it allows the calibration parameters to vary through the year. However, we believe that explicitly modelling seasonality has some benefits, and will be the method of choice in the long run. This is because:

- Fitting calibration parameters from the previous 90 days suffers from the problem that the parameters are always slightly behind relative to the present point in the season. They may be the best parameters for 45 days ago, but will not be the best parameters for today.
- Fitting calibration parameters from the previous 90 days only allows us to use a small amount of past forecast data for estimating the parameters. As the amount of available past forecast data increases it makes sense to try and use all of this data. This is especially important if we are to make use of the subtle signals contained in the varying spread of ensemble forecasts.

In section 2 we discuss the data we use for our study. In section 3 we describe the models and how we will compare them. In section 4 we present the results, and in section 5 we present our conclusions and discuss areas for future work.

2 Data

We will base our analyses on one year of ensemble forecast data for the weather station at London's Heathrow airport, WMO number 03772. The forecasts are predictions of the daily average temperature, and the target days of the forecasts run from 1st January 2002 to 31st December 2002. The forecast was produced from the ECMWF model (Molteni et al., 1996) and downscaled to the airport location using a simple interpolation routine prior to our analysis. There are 51 members in the ensemble. We will compare these forecasts to the quality controlled climate values of daily average temperature for the same location as reported by the UKMO.

There is no guarantee that the forecast system was held constant throughout this period, and as a result there is no guarantee that the forecasts are in any sense stationary, quite apart from issues of seasonality. This is clearly far from ideal with respect to our attempts to build statistical interpretation models on past forecast data but is, however, unavoidable: this is the data we have to work with.

Throughout this paper all equations and all values are in terms of double anomalies (have had both the seasonal mean and the seasonal standard deviation removed). Removing the seasonal standard deviation removes most of the seasonality in the forecast error statistics, and partly justifies the use of non-seasonal parameters in the statistical models for temperature that we propose.

3 Models

As mentioned in the introduction, we will take a *classical statistical* approach to the problem of creating probabilistic temperature forecasts. This means that we will postulate models which predict the distribution of temperature directly in terms of a number of predictors. Such models are simple to design, simple to understand, simple to fit, simple to test and easy to use for making forecasts. They also allow us to incorporate any number of predictors, including climatology, in an optimum (likelihood maximising) way. The standard method for estimating the parameters of classical statistical models is to find those parameters which maximise the probability of the observations given the model. This quantity, when considered as a function of the model parameters, is known as the likelihood. A standard (and intuitively very reasonable) way to compare such models against each other is to compare the maximum likelihoods they

achieve. The forecast that gives the higher likelihood (or log-likelihood) is the better forecast (see Jewson (2003e) and Jewson (2003d) for more details on this). This method for comparing probabilistic forecasts can be used on both continuous and discrete forecasts, and in-sample or out-of-sample. In-sample testing has two caveats: firstly that it can only be applied to parsimonious parametric models (because non-parametric models and models with large numbers of parameters are overfitted) and secondly that the probability used in the comparison has to be adjusted to penalise models with more parameters. A common way to make this adjustment is to use the AIC criterion, and the AIC score is what we will use below.

We now present the models we compare in this study.

Our first model is simply linear regression between temperature on day i (T_i) and the ensemble mean on day i (m_i), which we write as:

$$T_i \sim N(\alpha_0 + \beta_0 m_i, \gamma_0) \quad (1)$$

This model corrects biases using α_0 , optimally "damps" the variability of the ensemble mean and merges optimally with climatology using β_0 , and predicts flow-independent uncertainty using γ_0 . The bias and the uncertainty produced by this model vary seasonally because of the deseasonalisation and reseasonalisation steps. All our subsequent models will be judged against this model.

Our second model generalises this model so that the parameters themselves vary seasonally:

$$T_i \sim N(\alpha_i + \beta_i m_i, \gamma_i) \quad (2)$$

where

$$\begin{aligned} \alpha_i &= \alpha_0 + \alpha_s \sin \theta_i + \alpha_c \cos \theta_i \\ \beta_i &= \beta_0 + \beta_s \sin \theta_i + \beta_c \cos \theta_i \\ \gamma_i &= \gamma_0 + \gamma_s \sin \theta_i + \gamma_c \cos \theta_i \end{aligned} \quad (3)$$

where θ_i is the time of year. We have represented seasonality in the simplest way possible by using just one harmonic in order to keep the number of parameters as low as possible.

We now consider three models that are intermediate between the constant-parameter linear regression (equation 1) and the seasonal-parameter linear regression (equation 2).

The first only has seasonal bias correction:

$$T_i \sim N(\alpha_i + \beta_0 m_i, \gamma_0) \quad (4)$$

The second has seasonal damping:

$$T_i \sim N(\alpha_0 + \beta_i m_i, \gamma_0) \quad (5)$$

and the third has seasonal innovations:

$$T_i \sim N(\alpha_0 + \beta_0 m_i, \gamma_i) \quad (6)$$

For comparison we will also consider the spread regression model of Jewson et al. (2003):

$$T_i \sim N(\alpha_0 + \beta_0 m_i, \gamma_0 + \delta_0 s_i) \quad (7)$$

(where s_i is the ensemble spread on day i) and a completely seasonal version of the spread regression model:

$$T_i \sim N(\alpha_i + \beta_i m_i, \gamma_i + \delta_i s_i) \quad (8)$$

where

$$\begin{aligned} \alpha_i &= \alpha_0 + \alpha_s \sin \theta_i + \alpha_c \cos \theta_i \\ \beta_i &= \beta_0 + \beta_s \sin \theta_i + \beta_c \cos \theta_i \\ \gamma_i &= \gamma_0 + \gamma_s \sin \theta_i + \gamma_c \cos \theta_i \\ \delta_i &= \delta_0 + \delta_s \sin \theta_i + \delta_c \cos \theta_i \end{aligned} \quad (9)$$

This last model has the greatest number of parameters of all the models we consider (12) and would be expected to perform the best because it includes all the other models.

We fit the parameters of all the models by maximising the likelihood using a standard quasi-Newton method with finite-difference gradient.

4 Results

Figure 1 shows the AIC scores for the constant parameters and seasonal parameter linear regression models (upper and lower solid lines respectively). By definition, lower values of the AIC score are better, and a value of zero would be a perfect forecast. We see a *vast* improvement in the skill of the probabilistic forecast as a result of using seasonal parameters, especially at short lead times. The dotted line shows the AIC score for the seasonal spread regression model. There is a further improvement at most lags from making the spread calibration parameters seasonal in addition, but it is small. At lag 9 the fitting of the parameters of the spread regression failed: the algorithm was unable to find a convincing maximum for the likelihood. This is presumably because the signal is too weak given the number of parameters we are trying to fit and the amount of data being used.

Where does this vast improvement come from? Is it the seasonality in the bias correction, the damping, the innovations, or all three in combination together? We address this question using the intermediate models. Figure 2 shows the same results as figure 1 in the solid lines in each panel, but also shows the AIC score for 4 other models as a dotted lines (the top left panel is the seasonal bias model, top right is the seasonal damping model, lower left is the seasonal noise model and lower right is the non-seasonal spread regression model). We immediately see that, of these models, the seasonal bias model gives the greatest benefit over straight linear regression. Figure 3 shows the same data, but now relative to the AIC score of linear regression (more negative values are better). We see again that the seasonal bias correction gives a large benefit, the seasonal damping gives no real benefit, the seasonal noise gives a small benefit at short leads, and that the spread regression gives a small benefit at all leads.

Figure 4 investigates the extent to which there is *synergy* between the different parameterisations. In the upper panel we compare the benefit from making all of α, β and γ seasonal at once (dotted line) against the sum of the benefits of making them seasonal separately (solid line). There is definitely some synergy: the total is greater than the sum of the parts. In the lower panel we consider the benefit of using spread regression in a non-seasonal and seasonal model. In our previous research it has been rather disappointing that using the ensemble spread brings so little benefit to probabilistic forecasting, and we had hoped that maybe the benefit would be greater in the context of seasonal parameters for the mean. However, this is not the case. The benefit is more or less the same and is still very small.

Constant parameter linear transformations such as the basic linear regression model cannot improve the linear correlation of the ensemble mean with the observations. However, seasonal parameter linear transformations can. Figure 5 shows linear correlations before (solid line) and after (dotted line) the seasonal transformation. We see a definite improvement in linear correlation at all lead times.

Figure 6 shows the 9 parameters for the seasonal regression model. The top row shows the alpha parameters, the second row the beta parameters and the third row the gamma parameters. We see that the variability in alpha is dominated by the cosine term at all but the longest leads, the variability in beta is small relative to the average level of beta, and that gamma is more or less constant throughout the year (but not with lead, of course).

The final figure, figure 7, shows the seasonal variability of alpha predicted by the seasonal bias model for the first 9 lead times. We see that there is significant seasonal variability in the alpha predicted by the model, which is consistent with the large effect that this model had on the AIC score. We see that at short leads the smallest values of α are in spring and the largest in autumn, while at longer leads the opposite is true.

5 Summary

We have made *another* attempt at improving the probabilistic forecasts of temperature that can be made from ensemble forecasts. As before our starting point and basis for comparison is a linear regression model. Our previous attempts, that have looked at the benefit from using the ensemble spread (Jewson et al. (2003) and Jewson (2003c)) and the benefit from using the distribution of the individual ensemble members (Jewson, 2003b), have not shown much improvement over linear regression. This time we have tried allowing the parameters of the regression model to vary seasonally. We find a *dramatic* improvement in the skill of the forecasts, much larger than the improvement from our previous attempts. When we break down which terms are driving the improvement in skill we find that adding seasonality in the bias is the most important factor. However seasonality in all three terms is important and there is actually synergy between the terms such that the benefit from making all three regression parameters seasonal is greater than the sum of the benefits of making each one seasonal separately (by the measure we use for skill). Furthermore, our seasonal regression model also improves the linear correlation between forecast and observations.

The clear implication of this is that one should always use the seasonal parameter regression model in preference to the constant parameter linear regression model, and that the seasonal parameter regression model should become the new baseline for comparison with other methods and models.

There are, as ever, a number of avenues for future work that are suggested by this study. Most obviously, allowing the bias to vary seasonally seems to be so important that one could try using more harmonics. It may well be that adding extra parameters in the modelling of the bias is more useful than adding extra parameters elsewhere. We do not, however, feel it would be justified with only the limited amount of data used in this study, and this is why we have not considered higher harmonics here.

At a technical level, our fitting algorithm could be improved if we avoided the assumption that the forecast errors are uncorrelated in time (they are, in fact, weakly positively correlated). This may affect the results somewhat, but we doubt it would affect them qualitatively.

One possible criticism of our study might be that, by using up to 12 parameters to model only 365 (weakly correlated) observation pairs we are flirting with overfitting. We wouldn't disagree. We have compensated for this by using AIC rather than straight log-likelihood as our measure of skill and so it should be the case that our results would transfer to out of sample likelihood comparisons. Nevertheless if longer data sets of stationary past forecasts ever become available then it would be very interesting to repeat this analysis: the parameters of the models we have presented will become much better estimated, and the results that much better justified.

Our highest priority is now to repeat this analysis on wind and precipitation forecasts, which present similar but different challenges to the modelling of temperature because they are not close to normally distributed.
